Using Stable Isotopes to better understand the Petrologic and Hydrothermal Evolution of Cretaceous Linga Complex of the Peruvian Coastal Batholith, near Ica

González Olivares, Luciano U. 1, Clausen, Benjamin L2, Holk, Gregory J3, Poma, Orlando4

ABSTRACT

Oxygen and hydrogen isotope values obtained from 64 minerals separated from 18 samples are employed to determine the source of magma and hydrothermal fluids that caused potassic, propylitic, phyllic, and argillic alteration in the Linga complex, situated near Ica in the mid-to-late Cretaceous Linga 96-97 Ma Peruvian Coastal Batholith (Moore 1984 & Beckinsale 1985).

Calculated δ18O plagioclase values in fresh samples are between +6.7‰ and +7.9‰ at equilibrium with 16O/18O crystallization temperatures between 588°C and 654°C. A slight west-to-east and older-to-younger increasing trend in δ18O values for fresh samples suggests a slightly greater crustal component to the east. Pervasive potassic and propylitic alteration assemblages yielded average values for δ18O of +7‰ and for δD of -50‰ suggesting that alteration was primarily caused by magmatic fluids; however, other fluids were also involved. High plagioclase (+9.3‰) and hornblende (+6.3‰) δ18O values from one sample near a pluton contact suggest interaction with metamorphic or low temperature fluids. High epidote δD values from altered diorite (-25.8‰) and monzonite (-36.1‰) suggest seawater infiltration west of the batholith. The average water/rock ratio of 0.1 suggests 1 part of external meteoric or metamorphic fluids to 10 parts rock or magmatic fluids, indicating the significant role of magmatic hydrothermal fluids in the alteration.

RESUMEN

Los valores isotópicos de oxígeno e hidrógeno de 64 minerales aislados de 18 muestras se usaron para conocer el origen de los fluidos hidrotermales que causaron alteración potásica y propilítica desarrollada en el complejo Linga cerca de Ica del Batolito Costero Peruano del Cretácico medio-superior 96-97 Ma (Moore 1984 & Beckinsale 1985).

Valores de δ18O plagioclasa, en roca fresca, varían de +6.7‰ a +7.9‰ en equilibrio con temperaturas de cristalización de 18O/16O entre 588°C a 654°C. El leve incremento de oeste-este de más antiguos-recentes en valores δ18O de muestras frescas sugiere un componente cortical ligeramente mayor hacia el este. Ensamblés de alteración pervasiva potásica y propilítica dieron valores promedio de +7‰ en δ18O y -50‰ en δD, sugiriendo principalmente alteración por fluidos magnéticos. Sin embargo, otros fluidos también se involucraron. Altos valores de δ18O (+9.3‰) plagioclasa y δ18O (+6.3‰) hornblenda de una muestra cerca de un contacto plutónico, sugieren interacción con fluidos metamórficos o fluidos de baja temperatura. Altos valores en δD epidota (-25.8‰) de diorita alterada y de monzonita (-36.1‰), sugieren infiltración de agua marina al oeste del batolito. El valor promedio de 1/10 en la ratio agua/roca indica una parte de agua meteórica externa o fluidos metamórficos por 10 partes de fluidos magnéticos, indicando alteración principalmente por el rol de fluidos magnéticos hidrotermales en la alteración.

Magma experiences numerous changes in composition during transport from its source to the site of emplacement or eruption (Rutherford and Devine, 2003; Sykes, 1987). In particular, changes in stable isotopic composition occur as magmas are affected by partial melting (Williams et al., 2009), contamination (Garcia et al., 2008; Harris and Chaumba, 2001; Santo and Pecceirillo, 2008), magma mixing (Bindeman, 2008; Johnson et al., 1996), fractional crystallization (DePaolo, 1981; Sparks and Huppert, 1984), degassing (Taylor, 1986), and hydrothermal alteration (Dilles et al., 1992; Grunder, 1992; Harris and Golding, 2002).

Stable isotope studies have shown that subsolidus hydrothermal processes that affect plutons emplaced near Earth’s surface are the result of water from different sources that metamorphic (Giacchetti et al., 2015; Plank et al., 2013), metamorphic (Barnes, 1970; Yardley and Cleverley, 2013), oceanic (German and Lin, 2004; Humphris, 1976; Rohling, 2013), connate (Husband, 1998), and meteoric waters (Bowen and Revenaugh, 2003; Brandriss et al., 1995; Terzer et al., 2013). All can serve as ore-forming fluids (Guilbert and Park, 1986; Hedenquist and Lowenstern, 1994; Jibak, 1997; Robb, 2005). Other components in these solutions, such as dissolved ions and gasses, yield significant additional information about the pressure-temperature evolution of the solution and the fluid pH and oxidation state (Markl and Baumgartner, 2002; Rose and Burt, 1979; Taylor, 1986). Lithologies with which the fluid has interacted along its flow path influence these variables through alteration reactions (Mysen, 2014; Seyfried et al., 1988).

The origin of magmas and hydrothermal fluids at the Linga complex in the northern Arequipa segment of the Cretaceous Peruvian Coastal Batholith near Ica, is investigated using stable isotopes from fresh rocks and the various alteration facies recorded in them. Mineral δ^{18}O and δD values from unaltered rocks yield insight into magma sources and how they differ with location, age, composition, and apparent temperature. Style and temperatures of alteration and the areal extent of alteration are identified in the field and in thin section. Hydrothermal fluid sources and water/rock ratios are indicated by δ^{18}O and δD values from these altered rocks.

1. INTRODUCCIÓN

Earth, with its hydrosphere, active lithosphere and upper mantle, has an enormous potential to trigger a variety of interactions between aqueous fluids and rocks. Oxygen and hydrogen isotopes are valuable for understanding these interactions because they can help identify fluid sources, pathways and flux estimates (Brandriss et al., 1995; Sharp, 2007; Taylor, 1978). Stable isotope studies of numerous igneous rock suites have dramatically transformed our perspective on the role of such fluids in the evolution of the crust (e.g., Gregory and Criss, 1986).

2. GEOLOGIC SETTING

2.1. The Peruvian Coastal Batholith (PCB)

The Andes Cordillera is the largest and longest-lived active subduction-related orogeny on Earth (Schilling et al., 2006; Springer, 1999). It results from subduction of the oceanic Farallon Plate and later the Nazca Plate under the continental crust of the South American Plate beginning in the Cretaceous (Martinod et al., 2010; Pfiffner and Gonzalez, 2013; Polliand et al., 2005).

Convergence rates between these two plates increased dramatically during the late Early to Late Cretaceous and shifted to having a significant oblique component (Jaillard and Soler, 1996; McQuarrie et al., 2005; Mégard, 1984); this resulted in a trenchward motion of the South American plate, subduction erosion (Jaillard and Soler, 1996; Polliand et al., 2005), significant arc magmatism, and the emergence of volcano-sedimentary basins of the Mesozoic Western Peruvian Trough (Mégard, 1984; Pfiffner and Gonzalez, 2013). The development of this trough was followed by the intrusion of magmas between about 100 Ma and 30 Ma ago that yielded the numerous plutonic suites that comprise the Peruvian Coastal Batholith (PCB) shown in Figure 1 (Polliand et al., 2005; Soler and Bonhomme, 1990).

The PCB has a geometry and composite nature similar to other circum-Pacific batholiths, but is one of the largest. In addition, the PCB has preserved its integrity unlike the batholiths of western North America which have been partially disarticulated by later tectonic events, obscuring their relationships with the plate margin at the time of emplacement (Atwater, 1970; Schweickert and Cowan, 1975; Winter, 2010).

The abundant intrusions that comprise the Mesozoic-Cenozoic PCB constitute an exceptional example of long-lived plutonism related to a convergent margin. This batholith, parallel to the contemporary Peru-Chile trench along almost its entire 2000 km length, displays significant longitudinal differences in magma type and emplacement history, dividing into five segments. From north to south these segments are termed Piura, Trujillo, Lima, Arequipa, and Toquepala (Figure 1). Each segment is characterized by its own particular suite of intrusions which can be grouped into Super-units, and each Superunit comprises a set of units closely related in space, time, chemistry, and petrology (Cobbing and Pitcher, 1972; Cobbing et al., 1977; Moore, 1984).

The 900 km-long Arequipa segment, the longest of the PCB, extends from the Lurin District in the Lima Province southeast to Arequipa. This segment has been broadly mapped, with some of the most thorough mapping in the Rio Pisco and Rio Ica areas, providing detailed documentation of emplacement and petrologic processes (Agar, 1978; Cobbing et al., 1977; Moore, 1979).
2.2. **Brief description of rock units in the Ica-Pisco section of the PCB**

Rock units mapped in the Rio Ica and Rio Pisco section of the Arequipa segment of the PCB are shown in Figure 2. The Quilmana and Yura are Pre-PCB volcanic-sedimentary units primarily to the west and east of the PCB respectively. Early magmatic activity related to the PCB consists of gabbros. Then the Linga, Pampahuasi, Tiabaya, and Incahuasi Super-units form the main granitic units of the PCB.

Of the two major Pre-PCB volcanic-sedimentary units, the Yura group on the east is older. It has a thickness of 2000 m in the Rio Ica and up to 600 m of quartzite with interbedded shales northeast in the Rio Pisco (Moore, 1979). The Yura group in the eastern Rio Pisco area also includes volcanics (porphyritic andesites). The age of the Yura group is constrained to between 216 Ma and 134 Ma (Boekhout et al., 2013, see Alvan et al., ). The Quilmana volcanics, whose maximum emplacement age is about 113 Ma (Moore, 1979; Mukasa, 1986), dates back to the emergence of the Western Peruvian Trough (Aguirre and Offler, 1985). This unit includes the younger stratified rocks cut by the PCB and constitute a large part of its western and eastern envelope. The main lithology is metamorphic hornfels and the most abundant alteration minerals are biotite and epidote (Moore, 1979).
Gabbros that have been interpreted to correspond to the Patap gabbros in the Lima segment (Mukasa, 1986) are minor plutons broadly spread over a large part of the Arequipa segment. Previously the age of gabbroic plutons in the Ica-Pisco area has been bracketed between the 113 Ma Aptian/Albian boundary as the maximum emplacement age of the Quilmana volcaniclastics, which they intrude, and the 101.4 Ma concordant zircon crystallization ages of the oldest granitoids that cut the gabbros (Moore, 1979; Mukasa, 1986). However, Martinez (2016) found an age of 131 Ma for these gabbros and suggested that gabbros with younger ages may be cumulates of the PCB granitoids.

The Linga complex, the focus of this paper, is at the western margin of the PCB. This unit ranges from monzogabbro to monzogranite composition. In the monzogabbros and monzodiorites, cumulose textures are well preserved whereas granophyric textures, which suggests rapid cooling at shallow depths, prevail in the monzogranitic units (Agar, 1981; Mukasa, 1986). This consanguineous suite of intrusive rocks is interpreted to have originated from magmatic differentiation of a single parent magma (Agar, 1978) and is divided into three units: the Humay, Auquish and Rinconada (Agar, 1981). The earliest Humay unit is the most mafic and is comprised of quartz monzodiorite, quartz monzogabbro and monzogabbro. Mafics are present as small clots and subhedral prisms of hornblende as well as small flecks of biotite. This elongate unit is exposed along the western edge of the Linga complex and follows the Andean trend. Martinez (2016) determined no age for this unit, but inferred that it must be older than the 105 Ma Auquish unit which it intrudes. One of the main differences between the Humay Monzogabbro and the Humay Monzodiorite units is their K2O content, 1.2% for the former and 2.4% or the latter (Agar, 1981).

The 105-103 Ma (Martinez, 2016) Auquish unit is mostly porphyritic monzogranites and quartz monzodiorite. Mineralogy consists of hornblende, orthoclase and quartz, as well as varying proportions of accessory minerals. This unit is located northeast of the Humay unit and has a geometry like a ring complex. The Auquish monzodiorite unit belongs to a group of nested arcuate plutons and is particularly xenolithic immediately below its roof (Agar and Le Bel, 1985). The Auquish monzonite unit is characterized by relatively straight local schlieren layering and abundant mafic enclaves at its contacts with the Humay unit (Martinez, 2016).

The 100-96 Ma (Martinez, 2016) Rinconada unit is mostly monzogranite, characterized by grey-pink feldspar, pale plagioclase and quartz as well as small prisms of hornblende and sparse biotite. This unit outcrops in the
southern part of the Linga complex and has an elliptical spatial distribution (Agar and Le Bel, 1985; Moore, 1979). Large elongate and steep-walled plutons of the 98-90 Ma (Martinez, 2016) Pampahuasi Super-unit in the Arequipa segment are characterized by diorite and tonalite with well-developed mineral fabrics and localized shear banding (Moore, 1979; Mukasa, 1986). Plagioclase is coarse-grained and euhedral, and hornblende is present with poikilitic biotite.

The 87-82 Ma (Martinez, 2016) Tiabaya Super-unit is distinguished by hornblende and biotite occurring as euhedral grains and plagioclase appearing as crystals up to 1 cm long. The lithology is made up of tonalite, granodiorite and quartz monzonite. This unit occurs extensively throughout the Arequipa segment (Agar, 1978).

The 69-58 Ma (Martinez, 2016) Incahuasi Super-unit is characterized by pervasive poikilitic hornblende and biotite in a framework of euhedral plagioclase. Its main lithology is quartz diorite to monzogranite (Agar, 1978).

### 3. PREVIOUS STABLE ISOTOPE STUDIES IN THE PCB

Few stable isotope data exist for the PCB. Beckinsale et al. (1985) report whole rock δ¹⁸O values between +6.3‰ and +8.6‰ (n = 11) for fresh samples from the Sayán pluton (Figure 1) 150 km north of Lima in the Lima segment. These data are interpreted to be the product of fractional crystallization (Taylor, 1978).

More data exist for portions of the PCB that have been affected by hydrothermal systems related to mineralization. Phengite δD values of −67‰ to −47‰ and calcite δ¹⁸O values of +15‰ to +30‰ (Le Bel, 1985) suggest a magmatic origin for alteration fluids at the Cerro Verde porphyry Cu deposit near Arequipa (Figure 1); however, high calcite δ¹⁸O values at high structural levels suggest the involvement of meteoric hydrothermal fluids at low temperatures (< 100°C).

Another study was done at the Raul mine, a complex metamorphosed strata-bound vein-rich sulphur deposit (De Haller et al., 2006; Ripley and Ohmoto, 1979) 150 km south of Lima (Figure 1). It revealed amphibole δD values of −60‰ to −21‰ (n = 15), whole rock δ¹⁸O values of +7.8‰ to +10.8‰ (n = 11), and vein calcite δ¹⁸O values of +14.0‰ to +14.2‰ (n = 2). These data suggest the involvement of seawater modified by evaporation and/or shale membrane processes during mineralization (Ripley and Ohmoto, 1979).

---

**Figure 3. a)** Outcrop at the Pampahuasi-Humay boundary with abundant K-feldspar, biotite and magnetite indicating potassic alteration probably at temperatures of 450 to 600°C.

**Figure 3. b)** Outcrop at the Pampahuasi-Humay boundary with widespread epidote indicating propylitic alteration probably at temperatures of 250 to 350°C. Both outcrops are in the Rio Cansas transect.
4. HYDROTHERMAL ALTERATION IN THE LINGA COMPLEX

Potassic, propylitic, and sericitic alteration are common in units of the Linga complex. The alteration patterns are frequently organized concentrically in areas surrounding the intrusion with the potassic alteration in the center and the propylitic alteration toward the edge of the pluton (Agar, 1981).

Potassic alteration (Figure 3a) results from potassium enrichment. It is particularly abundant and important in porphyry and epithermal mineralizing systems where it occurs in the high temperature core zones.

Potassium silicate alteration results from the replacement of plagioclase and mafic silicate minerals with K-feldspar and secondary biotite/sericite (Figure 4a) at temperatures of 450°C to 600°C (Pirajno, 2009). This type of alteration can occur before complete crystallization of magma (Damian, 2003; Rose and Burt, 1979).

Propylitic alteration (Figure 3b) is characterized by the addition of H₂O and CO₂ with no substantial acidic metasomatism. It becomes more pervasive close to the heat and fluid source of a hydrothermal deposit (Pirajno, 2009) and normally forms at 250°C to 350°C (Dilles et al., 1992; Hedenquist et al., 2000). Characteristic mineral assemblages of propylitic alteration are albite, chlorite, epidote, carbonates, sericite, pyrite and magnetite (Figure 4b), mostly replacing plagioclase (Rose and Burt, 1979).

Phyllic alteration is common in granitic intrusions related to porphyry copper and other vein-alteration ore deposits (Que and Allen, 1996). Both potassium feldspar and plagioclase are converted to sericite and minor amounts of clay minerals (Figure 4c) (Rose and Burt, 1979). Sericitization in the phyllic facies generally occurs between 200° and 350°C (Hedenquist et al., 2000; Meunier and Velde, 2004).

Argillic alteration (Figure 4d) results from the total conversion of feldspar and amphiboles to the low temperature (< 200°C) minerals dickite, kaolinite, and montmorillonite, along with sericite and other clay minerals. This style of alteration is related to leaching of calcium, sodium and magnesium by acidic fluids (Pirajno, 2009; Rose and Burt, 1979).

---

Figure 4. Thin sections (with crossed-polars) of four types of alteration mentioned in the text and observed in the Linga complex. a) Potassic alteration in sample 14714Ca from the border between Humay and the volcanics in the Quebrada Larga transect. Note the secondary biotite (Bt) veinlets cutting plagioclase (Pl) crystals and the groundmass and magnetite (Mt). b) Propylitic alteration in sample 14723D from the border between Humay and Pampahuasi. Note the abundance of epidote (Epi) and chlorite (Ch). c) Phyllic alteration in sample 13828A in the Rio Pisco transect with sericite (Ser) replacing plagioclase (Pl). d) Argillic alteration in sample 14714Cb from the border between Humay and the volcanics in the Quebrada Larga transect with a clay mineral, probably kaolinite (Kln), replacing plagioclase.
5. ANALYTICAL TECHNIQUES

Most samples were collected along southwest to northeast trending rivers that cut the Linga complex in the Ica-Pisco area. Transects include the Quebrada Cansas, Rio Ica, Quebrada Larga, and Rio Pisco (Figure 2) with focus on contact zones between Super-units to identify styles of hydrothermal alteration. Published geologic maps of the Guadalupe and Ica quadrangles (INGEMMET, 1978) guided these efforts. Rock samples selected for isotopic analysis are representative of the Super-units in this part of the PCB. Petrographic analysis identified the style of alteration and minerals available for isotope analysis. Minerals were separated from 18 samples by Yu-Neng Mineral Separation Co., Langfang, China.

All stable isotope measurements were performed using the ThermoFinnigan DeltaPlusXP mass spectrometer at the Institute for Integrated Research in Materials, Environments and Societies at California State University, Long Beach. Oxygen was extracted from silicate minerals using a modified version of the laser fluorination method (Sharp, 1990). Oxygen isotope values are reported relative to V-SMOW, where NBS-28 has δ18O = +9.6‰ on this scale. Replicate analyses of Caltech rose quartz working standard (δ18O = +8.45‰) have an analytical error of ±0.2‰. Water content of minerals analyzed for hydrogen isotopes was determined by comparing the area under the gas chromatograph peak for mass 2 to a calibration of area versus sample size for NBS-30 biotite (3.5% H2O). Quality control and reproducibility is shown by duplicate measurements on 20% of samples analyzed for oxygen isotopes and all samples analyzed for hydrogen isotopes.

6. RESULTS

Table 1 shows 48 δ18O values and 16 δD values acquired from 18 samples from the Ica-Pisco section of the PCB.

Seven samples are fresh and eleven are altered. This table also shows four estimated δ18O values for plagioclase. Sample locations are indicated in Figure 2.

6.1 Unaltered intrusive rocks

The δ18O values in Table 1 are from rocks that belong to each of the Super-units with the range of values for each mineral from unaltered rocks being: quartz (+9.1 to +9.8‰, n = 4), K-feldspar (+7.4 to +8.2‰, n = 3), plagioclase (+6.7 to +7.9‰, n = 7), hornblende (+5.5 to +6.2‰, n = 5), and biotite (+3.9 to 5.5‰, n = 4). The values are consistent with a continental magmatic arc origin (Taylor and Sheppard, 1986). Likewise, biotite (–80.8 to –74.5‰, n = 4) and hornblende (–86.7 to –63.9‰, n = 5) δD values are primary magmatic values.

6.1.1 Primary magma sources

Plagioclase δ18O values from unaltered rocks increase from approximately +7‰ to +8‰ in a west-to-east direction (Figure 5). The same data is displayed in Figure 6 by decreasing age from approximately +7‰ at 130 Ma to +8‰ at 70 Ma.

Figure 5. Values of δ18O for fresh samples ordered from west to east. Note the slight increasing trend resembling that in the Peninsular Ranges Batholith of California (Clausen et al., 2014; Schmidt and Paterson, 2002; Silver et al., 1979). The error bars are ±0.2‰. Errors come from the California State University Long Beach CSULB isotope laboratory.

Figure 6. Values of δ18O for fresh samples ordered from older to younger. Note the slight increasing trend as the rocks become younger, which corresponds to the west-to-east trend shown in Figure 5. The error bars are ±0.2‰. Errors come from the CSULB isotope laboratory.
Table 1. Oxygen and hydrogen isotope values in units of per mil for fresh and altered (*) samples. Blue colored values were estimated based on the $\delta^{18}O$ values of other minerals in the same mineralization assemblage (Bottinga and Javoy, 1975). Quartz (Qtz), K-feldspar (Kfs), plagioclase (Pl), hornblende (Hbl), actinolite (Act), Biotite (Bt), epidote (Epi), and magnetite (Mt).

These increasing values indicate the incorporation of more crustal material from west to east and with time. Since the range in $\delta^{18}O$ values is so small, error bars of ±0.2‰ are included in Figures 5 and 6.

The west-east increase of +6.7 to +7.9‰ is smaller than the range observed for whole rock $\delta^{18}O$ values from the Peninsular Ranges Batholith (+6‰ to +12‰, Silver et al., 1979). Contaminated mantle melts display a rise in $\delta^{18}O$ values in correlation with increasing SiO$_2$ (Hoefs, 1996). The trend of $\delta^{18}O$ in the Peninsular Ranges Batholith indicates a mantle magma source in the west contaminated by an $^{18}O$ source increasing eastward. In contrast, our data indicate only slight contamination of primary magma from a mantle source for the PCB in the Ica-Pisco area. This is consistent with a restricted range of depleted mantle initial $^{87}Sr/^{86}Sr$ (Sr$_i$) values (0.7036-0.7065) observed in Ica-Pisco area (Martinez et al., 2016) with slight increases of Sr$_i$ toward the northeast.

Near Arequipa, magmas related to the Arequipa segment intruded Precambrian cratonic rocks of the Arequipa massif, as well as Pre-PCB volcanic and sedimentary units. Increased contamination of crustal material is reflected by a much larger range of initial $^{87}Sr/^{86}Sr$ ratios from 0.7036 to 0.7084 (Beckinsale et al., 1985) and a slightly higher $\delta^{18}O$ value of +9‰ (Le Bel, 1985) from a pluton related to the Cerro Verde porphyry Cu deposit. For comparison, this range of Sr$_i$ values are similar to those from the Peninsular Ranges Batholith of 0.703 to 0.709 (Langenheim et al., 2004; Silver et al., 1979), another batholith displaying an eastward increasing crustal
component as magmatism shifted in that direction due to shallowing subduction. This trend is not as pronounced in the Peruvian batholith.

6.1.2 A test of $^{18}$O/$^{16}$O equilibrium and geothermometry for unaltered rocks

Closure temperatures can be estimated using $\delta^{18}$O values measured for all major minerals that comprise an intrusive rock along with the employment of $^{18}$O/$^{16}$O fractionation factors between quartz and each mineral (Bottinga and Javoy, 1975; Faure and Mensing, 2009). The temperature dependence of the isotopic fractionation factors of oxygen and oxide minerals are given by equations (Bottinga and Javoy, 1975) with the form

$$10^3 \ln a_b^a = A + \frac{B \times 10^6}{T^2}$$

where $\alpha$ is the isotopic fractionation factor between two coexisting minerals $a$ and $b$, $T$ is the temperature in Kelvins, and $A$ and $B$ are experimentally determined constants. Equation (1) is linear at temperatures > 300°C (Sharp, 2007) when plotted with $10^6/T^2$ as the x-axis and can be expressed as

$$\delta_a - \delta_b = \Delta_b^a = 10^3 \ln a_b^a = A + \frac{B \times 10^6}{T^2},$$

where $\delta_a - \delta_b = \Delta_b^a$ applies at temperatures > 300°C (Gregory et al., 1989). By designating quartz as mineral $a$, the B coefficient (Table 2) for each other mineral ($b$) is used to calculate equilibrium temperatures. If $a$ and $b$ are non-hydrorous minerals, then $A = 0$.

However, if the minerals such as amphibole and biotite contain hydroxyl groups, then the $A$ value is $-0.3$ and $-0.6$ respectively (Javoy, 1977). Equation (2) is useful in that the difference $\delta_a - \delta_b$ between various pairs of minerals can be used to determine the equilibrium temperature of the coexisting minerals (Bindeman, 2008; Javoy et al., 1970; Turi, 1988).

The resulting equilibrium temperature is equal or less than the temperature of crystallization, since the minerals may have continued exchanging oxygen isotopes while the rock was cooling after crystallization (Giletti and Hess, 1988). The oxygen isotope temperature is valid under the assumption that minerals are in equilibrium when isotope exchange ceased and that the mineral assemblage was not disturbed by interaction with sub-solidus external aqueous fluids (Faure and Mensing, 2009; Guilbert and Park, 1986).

Oxygen isotopic equilibrium can be tested graphically with the “isotherm method” of (Javoy et al., 1970) that uses the experimentally and theoretically determined $A$ and $B$ parameters of equation (2). According to this method, individual minerals from a rock that are in isotopic equilibrium fall on a straight line that crosses the zero-zero point (representing quartz), and whose slope $10^6/T^2$, yields apparent equilibrium temperature. This “isotherm method” yields better results if the number of mineral $\delta^{18}$O values is maximized and cover as large a range of $\delta^{18}$O values as possible, such as covering the range between quartz and magnetite (Holk et al., 2016).

The application of this method to unaltered samples reveals apparent isotopic equilibrium at temperatures between 588° and 654°C (Figure 7).

![Figure 7. Thermometry plots for four fresh samples from the Linga complex. Values of R2 greater than 0.9 indicate isotopic equilibrium between minerals. Temperatures were obtained using equation (2) in the text. Quartz (Qtz), K-feldspar (Kfs), plagioclase (Pl), hornblende (Hbl), biotite (Bt), magnetite (Mt).]
The highest equilibrium temperatures are from the Incahuasi granodiorite (654°C) and Pampahuasi diorite (639°C), but the latter result is from only three minerals. The Tiabaya granodiorite and the Linga Rinconada granite showed an apparent isotopic equilibrium at lower temperatures of 588 and 601°C, respectively.

6.2 Altered samples

Samples that display evidence for alteration in both the field and thin section have mineral δ18O values (Table 1) out of equilibrium, including quartz (+8.9‰), K-feldspar (+5.6 to +8.5‰, n = 3), plagioclase (+2.6 to +9.3, n = 11), hornblende (+3.6 to +6.3‰, n = 2), biotite (+0.1 to +3.3‰, n = 2), actinolite (+1.2‰), epidote (+3.2 to 3.5‰, n = 2), and magnetite (+0.5‰), that suggest interaction with external fluids of various types. This is supported by δD values from biotite (−86.5 to −73.8‰, n = 2), hornblende (−89.2 to −83.7‰, n = 2), actinolite (−78.6‰), and epidote (−36.1 to −25.6‰, n = 2).

6.2.1 Identification of fluid sources using isotope data based on altered samples

Stable isotope values from mineral and mineral-H2O fractionation factors can be used to identify the source of the hydrothermal fluids responsible for these sub-solidus mineralogical changes in the rock, if the alteration temperature is known. Such fluids (Figure 8) include seawater (δ18O and δD ~ 0‰; Faure, 1998; Rollinson, 1993), magmatic water (δ18O = +6 to +10‰, δD = −80 to −40‰; Sheppard, 1986), metamorphic waters (δ18O = +3 to +25‰, δD = −65 to −20‰; Guilbert and Park, 1986; Rollinson, 1993), and meteoric-hydrothermal water with variably low δ18O and δD values (Sheppard, 1986).

Isotopic values of meteoric water are governed by the Global Meteoric Water Line (GMWL) equation (Faure and Mensing, 2009; Yeh et al., 2014) whose mathematical expression is equation (3).

$$\delta D = 8\delta^{18}O + 10$$  \hspace{1cm} (3)

The values of $\delta D$ and $\delta^{18}O$ displayed by meteoric water are a function of geographic location, becoming increasingly lighter going from the equator to the poles and from coastal to inland areas (Bowen and Revenaugh, 2003; Ohmoto, 1986; Sharp, 2007).

Meteoric water in the Ica-Pisco section of the PCB has an average $\delta^{18}O$ value of approximately $-5\%_o$ (Bowen and Revenaugh, 2003). Thus, according to equation (3), $\delta D$ would be $-30\%_o$, assuming that these waters follow the Global Meteoric Water Line trend. However, the interaction of this low $\delta^{18}O$ meteoric water with plutonic intrusions in subduction environments causes an increase in water temperature (Ohmoto, 1996; Pirajno, 2009; Sharp, 2007; Taylor, 1979; Turi, 1988), which brings about a depletion of $^{18}O$ in both the pluton and the country rock and a corresponding $^{18}O$ enrichment or a "$^{18}O$ shift" in the meteoric water. This process causes plutonic rock to have very low and even negative values for $\delta^{18}O$ (Criss and Taylor, 1986; Taylor, 1978; Turi, 1988).

6.2.2 Water/rock ratio and intensity of fluid-rock interaction

When magmas are intruded into the shallow crust, crystallize, and cool, they work as gigantic "heat engines" that produce the energy necessary to support a long-lasting convective circulation system of any $H_2O$ in the country rocks. These waters are most commonly meteoric-hydrothermal water, if magmas were emplaced into a shallow crust subaerial environment (Criss and Taylor, 1986; Dilles et al., 1992; Brandriss et al., 1995) and seawater for a submarine system (Gregory and Taylor, 1981; Cathles, 1993; Holk et al., 2008). This interaction changes $\delta^{18}O$ and $\delta D$ values of both water and rock (e.g., Taylor, 1974). Nevertheless, unaltered igneous rocks have a definite range of isotopic values (Bindeman, 2008; Rollinson, 1993; Sharp, 2007) that can be used for comparison to determine the effects of any processes that considerably alter their $\delta^{18}O$ values (Taylor, 1974).

Oxygen isotope ratios of hydrothermally altered igneous rocks are useful data for determining the amount of water that has interacted with the rock (Larson and Zimmerman, 1991; Taylor, 1977). A first estimate of the amount of water involved in a closed meteoric hydrothermal system can be determined by the material balance equation (Gregory et al., 1989; Taylor, 1974),

$$W\delta_{H_2O} + R\delta_{\text{rock}}^i = W\delta_{H_2O}^f + R\delta_{\text{rock}}^f$$  \hspace{1cm} (4)

where $i =$ initial $\delta^{18}O$ value, $f =$ final $\delta^{18}O$ value after reaction, $W =$ atom percent of meteoric water oxygen in the whole system and $R =$ atom percent of rock oxygen in the total system. The water/rock ratio can be calculated by rearranging equation (4) to the form

$$\frac{W}{R} = \frac{\delta_{\text{rock}}^f - \delta_{\text{rock}}^i}{W\delta_{H_2O} - (\delta_{\text{rock}}^f - \delta_{\text{rock}}^i)}$$  \hspace{1cm} (5)
where $\Delta = \delta^f_{\text{rock}} - \delta^f_{\text{H}_2\text{O}}$ given by the application of the $^{18}\text{O}/^{16}\text{O}$ fractionation factor for the temperature of hydrothermal activity.

Values of $\delta^{18}\text{O}$ for fresh and altered samples are compared in Table 3, where equation (5) was used to estimate the water/rock ratio involved in the alteration.

Equation (5) was also used to determine the magnitude of change undergone by the $\delta^{18}\text{O}$ values of fresh samples during the alteration process as well as the type of fluid that probably caused the alteration.

7. DISCUSSION

To better understand the discussion below, it is important to remember that $\delta^{18}\text{O}$ values of coexisting minerals in isotopic equilibrium in unaltered granitic rocks, increase in the following order: magnetite-biotite- amphibole-muscovite-plagioclase-K-feldspar-quartz (Taylor, 1978) showing a general increase in $\delta^{18}\text{O}$ values with increasing wt% SiO$_2$. The relative values with respect to quartz for the minerals mentioned above as suggested by Bottinga and Javoy (1975) are summarized in Table 2. Park and Ripley (1999) suggest an estimated value of 5 for epidote in Table 2.

7.1 Classification of fresh samples based on their $\delta^{18}\text{O}$ values

Based on their whole rock $\delta^{18}\text{O}$ values, plutonic rocks can be classified into three types (Taylor, 1978): a) low $\delta^{18}\text{O}$ granitic rocks with $\delta^{18}\text{O} < +6\%$, b) normal $\delta^{18}\text{O}$ granitic rocks with $+6\% < \delta^{18}\text{O} < +10\%$, and c) high $\delta^{18}\text{O}$ granitic rocks with $\delta^{18}\text{O} > +10\%$. Since plagioclase is the most abundant mineral in igneous rocks, $\delta^{18}\text{O}$ values of plagioclase are the closest to the whole rock $\delta^{18}\text{O}$ value and would be considered representative, if the rock is demonstrated to be in $^{18}\text{O}/^{16}\text{O}$ equilibrium. Using the criteria above, it is clear that all $\delta^{18}\text{O}$ values for fresh samples in Table 1 that demonstrate equilibrium and escaped subsolidus hydrothermal alteration are in the normal range for granitic rocks.

The normal range of hydrogen isotope values for granitic rocks is –85‰ < $\delta^D$ < –50‰ (Taylor, 1978). A plot of biotite and hornblende $\delta^D$ values vs plagioclase $\delta^{18}\text{O}$ values (Figure 8) shows that most of these samples lie within the rectangular area labeled as the primary magmatic zone of Taylor (1974), consistent with the fresh condition of these rocks.

7.2 $\delta^{18}\text{O}$ values of altered samples

Hydrothermal alteration is a complex process involving mineralogical, chemical, isotopic, and textural changes caused by the interaction of hydrothermal fluids that circulate through rocks under variable and changing physiochemical conditions (e.g., Pirajno, 2009; Rose and Burt, 1979).

The circulation of hydrothermal fluids is greatly accelerated by faults whose occurrence enhances permeability (Fetter, 2001; Hartman et al., 2018). Joints and faults provide conduits that allow hydrothermal fluids to quickly migrate until they cool and precipitate their mineral content or react with and replace dissolvable country rocks, a process able to produce a variety of alteration types (Guilbert and Park, 1986). In accordance with the previous statements, Agar (1981) mentions that hydrothermal alteration observed in the Ica-Pisco section is associated with the circulation of hydrothermal fluids along faults. Figure 9 shows some of the faults in the Ica-Pisco section as well as the areas affected by different types of alteration.

Table 3. $\delta^{18}\text{O}$ values for plagioclase in altered samples with respect to fresh samples, displaying direction and magnitude of the alteration, probable fluid involved, and water/rock ratio calculated using equation (5) in the text.
Table 1 shows the δD and δ18O values for the 11 altered samples. Note that 5 out of 7 δ18O plagioclase values from altered samples belong to the normal range proposed by Taylor (1978). This suggests that the alteration of most samples was caused by hydrothermal fluid of magmatic origin (Sharp, 2007; Sheppard, 1986).

Altered samples whose plagioclase δ18O show values below those in equilibrium with magmatic fluids are from the Yura volcanics (14710G, δ18O = +2.6‰), the Linga-Auquish (14721Ac, δ18O = +5.5‰), and a sample associated with copper mineralization (14724Ac, δ18O = +5.7‰). These δ18O values are probably due to 18O/16O exchange with heated meteoric-hydrothermal water (Sharp, 2007; Taylor, 1978).

According to Table 3, the lowest water/rock ratio involved in the change of δ18O values is 0.03. This value belongs to the Quilmana volcanics sample 14714Cb whose variation is from +7.6‰ to +7.4‰. Since this is a decrease from the original value, the change may just be due to the margin of error in measurement (a 3% error introduces error bars of ±0.2‰ in the calculations), but could also be caused by a very small contribution of meteoric water. However, the decrease from +7.6‰ to +7.4‰ still remains in the interval of magmatic fluids, which suggests that the main interaction was with magmatic hydrothermal fluids.

The biggest increase in δ18O values from +7.2‰ to +9.3‰ belongs to sample 14716G from the metamorphic aureole where the Pampahuasi intrudes the Quilmana volcanics in the Rio Cansas transect. The water/rock ratio of 0.2 in Table 3 suggests that the increase may have resulted from the interaction of 1 part external metamorphic fluids with 5 parts rock or magmatic fluids. In fact the δ18O value for this altered sample is in the range of magmatic hydrothermal fluids.

The biggest decrease in δ18O values in Table 3 is from +7.5‰ to +2.6‰ and belongs to sample 14710G from the Yura group. The direction of the isotopic change as well as the high water/rock ratio of 1.6 suggest that large amounts of meteoric fluids may have been involved in the alteration. The dominance of meteoric hydrothermal fluids interacting with this sample is supported by the low δ18O value of biotite +0.1‰. The depletion in 18O value in this sample, agrees with the effect of magmatic intrusions heating water, bringing about a 18O enrichment of water and causing plutonic rock to reach very low and even negative values for δ18O.
7.3 $\delta D$ for fresh and altered samples

Hydrothermal fluids are a major source of various components of hydrothermal ore deposits formed in volcanic arcs. These components, including metals and their ligands, become concentrated in magmas in various ways from various sources, including subducted oceanic crust and leaching of rocks (Hedenquist and Lowenstern, 1994). Thus, the fact that most of the samples in Table 1, either fresh or altered, have $\delta D$ values in the normal isotopic range for plutonic rocks, i.e. $-85\% < \delta D < -50\%$, can be explained by noting that most primary magmatic water may have originated from OH-bearing minerals (clays, micas, amphiboles) of subducted sediments and altered volcanic rocks that have been introduced into the lower crust or the upper mantle through geologic time. These subducted materials are directly melted or dehydrated at high temperatures in the upper mantle, and the resulting hydrothermal fluid is incorporated into the calc-alkaline magmas produced in subduction-zone environments, like those producing the Linga complex of the PCB (Burnham, 1979; Hoefs, 1996; Stakes, 1991; Taylor, 1979; Wilson, 1989). Nevertheless, the high $\delta D$ – 25.6‰ value of sample 14723D and –36‰ for sample 14721B do not fit in the normal interval for $\delta D$ values of Taylor (1974). These values could be the result of interaction between the rock and seawater probably infiltrating the western side of the batholith.

8. CONCLUSIONS

An oxygen isotope closure temperature of 590°C to 650°C recorded for unaltered samples indicates the preservation of magmatic values and any fluids related to such rocks were magmatic in origin. The slight increase in $\delta^{18}O$ values of fresh samples from west to east and as ages get younger suggests an increased crustal contribution to these magmas with time and distance away from the continental margin.

Potassic ($\sim 450-600°C$) and propylitic alteration ($\sim 250-350°C$) dominates the center, and southeast and northwest extremes of the Linga complex, respectively. Phyllic ($\sim 200-350°C$) and argillic alteration ($\sim 100-200°C$) are present, but not as abundant in the Linga complex as the previously mentioned alteration types. Oxygen and hydrogen isotope data indicate that magmatic fluids were responsible for this alteration, but evidence is provided for limited involvement of meteoric–hydrothermal, metamorphic, and seawater fluids at small water/rock ratio.

ACKNOWLEDGMENTS
